European forest classifications

G. Caudullo, S. Pasta, F. Giannetti, A. Barbati, G. Chirici

Phytosociology

Phytosociology is a rather young discipline which started in Europe in the early decades of the last century with the Swiss botanist and ecologist Josias Braun-Blanquet\(^1\). This discipline is focused on describing plant communities through a multi-purpose approach, taking into consideration different parameters such as species composition, frequency, cover, structure (tree, shrub, herb, moss layers), spatial distribution (the so-called sociability; i.e. causal, clumped, etc.). The aim of phytosociology is to provide effective synthetic information about plant communities in order to assign them to different and recognizable units called syntaxa. Syntaxa are then grouped hierarchically within a classification system which is ruled by the ICNP (International Code of Phytosociological Nomenclature)\(^2\). Phytosociologists usually collect data through relevés recording the species occurrences within selected plot areas using a semi-quantitative cover-abundance scale. Collected data are then analysed looking for similarities and dissimilarities in order to detect distinct vegetation types. More recently several numerical models have been developed, which help to identify dominant and diagnostic species, to evaluate species-richness and species-evenness, and which can lead to a more objective classification of vegetation units\(^3\).

The hierarchical classification foresees, as the botanical one, different ranks. The association is the basic vegetation unit: it represents a plant community defined by a particular and uniform floristic composition and habitat structure, where a relative constancy or abundance of characteristic species is recognisable (called also diagnostic or dominant), which can describe the community and its ecology. The upper units are a group of lower ones, which share one or more diagnostic and dominants species\(^4\). Each unit is assigned a scientific name and is defined with compound names formed by one or two scientific names of the dominant and diagnostic plant species with a different suffix for each rank\(^5\).

The sector of phytosociology which deals with vegetation dynamics and aims at detecting successional series is known as symphytosociology. The vegetation series (or signetum) is a group of spatially and temporally interconnected vegetation units that may co-occur in different succession stages or steps within the same place. Progressive succession is the natural dynamic process from pioneer to mature and stable communities (the so-called ‘climax’ or head series), while regressive succession is a disruptive process from more complex communities to open and less developed plant assemblages; the latter mostly issues from intense and frequent anthropogenic disturbance.

In the last century a very large body of phytosociological literature has been published, and a variety of schools with different approaches formed, especially in southern and eastern Europe, while this approach found no or little consensus in the United Kingdom and in north European countries. Recently the European Vegetation Survey, a working group established in 1992, joined European phytosociologists in order to develop common standards, organize scientific meetings and survey programmes, and to produce shared protocols and publications\(^6\) ([http://euroveg.org](http://euroveg.org)). In the first overview of vegetation units, 80 classes, 233 orders and 928 alliances have been detected all over Europe\(^6\).

**EUNIS Habitat Classification**

The European Topic Centre on Biological Diversity (ETC/BC), an international consortium working with the European Environment Agency (EEA), developed the European nature information system (EUNIS), available at [http://eunis.eea.europa.eu](http://eunis.eea.europa.eu). This database provides information about European habitat classification, data sheets on species, habitats and protected sites compiled in the framework of Natura 2000\(^8\), and species mentioned in relevant international conventions and in the IUCN Red Lists. The EUNIS habitat classification is a hierarchical classification of the terrestrial, freshwater and marine habitats for the whole of Europe\(^8\). Up to now this classification provides a pan-European reference set of units for meeting requirements in policy objectives and in supporting applications that relate to biodiversity monitoring and reporting. A crosswalk from the EUNIS habitats at level 3 to the European phytosociological syntaxa and vice-versa is also available\(^9\).

**European Forest Types**

The European Forest Types (EFTs) scheme has been developed by an international consortium of experts with the aim to create a user-friendly classification system. It is, in fact, able to facilitate understanding, interpretation and communication of data on indicators describing the status and trends of forests, and forest management in Europe. The EFTs is a hierarchical classification consisting of 14 categories, including 78 forest types\(^10\). The 14 categories represent groups of ecologically distinct forest communities dominated by specific assemblages of trees, including introduced tree species, while the types correspond to a finer level of division of the category in terms of tree species composition. The EFTs is, therefore, a flexible system to compare forest information on ecologically similar forests, unlike other classification systems that present an
